Gamma-ray transitions in the extremely neutron-deficient nucleus  $^{106}\text{Te}$  have been identified for the first time. The experiment, which utilised the  $^{54}\text{Fe}(^{54}\text{Fe},2n)^{106}\text{Te}^*$  reaction, was performed at the K130 Cyclotron Accelerator Laboratory of the University of Jyväskylä, Finland. Prompt  $\gamma$  rays produced at the target position were detected by the JUROGAM  $\gamma$ -ray spectrometer and those belonging to  $^{106}\text{Te}$  were selected based on the recoil identification provided by the RITU gas-filled recoil separator and the GREAT focal plane spectrometer using the recoil decay tagging technique. The production cross section was estimated at 25 nb, a new limit for in-beam  $\gamma$ -ray spectroscopy. A ground state band, tentatively extending up to  $I^\pi = 8^+$ , is proposed suggesting enhanced vibrational collectivity as  $N \rightarrow Z$ . The systematics of low-lying yrast states in the Te isotopes is discussed within the context of vibrational excitations and residual nucleon-nucleon (in particular  $T = 0$  np) interactions.
