The structure of the very neutron-deficient rare-earth nuclei near the proton drip-line has been investigated in the first experiment with the EXOGAM gamma array coupled to the DIAMANT light charged particle detector and the wide angular and momentum acceptance VAMOS spectrometer using radioactive beam ^{76}Kr delivered by the SPIRAL facility at GANIL.

Microscopic Hartree-Fock-Bogoliubov calculations using Sly4 effective force have been performed in order to determine the proton drip-line position and the deformation of the neighbouring even-even Nd, Sm and Gd isotopes. The predictions of these calculations concerning the island of large ground state deformation in these nuclei will be presented.

Very proton-rich Pr, Nd and Pm isotopes have been populated at rather high spin by the fusion-evaporation reaction with a SPIRAL radioactive beam of ^{76}Kr ($T_{1/2} = 14.8\text{h}$) at 328 MeV bombarding ^{58}Ni target. For this experiment, the γ -array composed by 11 EXOGAM Ge segmented clover detectors was coupled to the DIAMANT detector system in order to measure the charged-particle evaporation residues and to the VAMOS spectrometer to determine the recoil nuclei.

During this experiment, the performances of the coupling of EXOGAM, DIAMANT and VAMOS have been demonstrated for the first time with fusion-evaporation reaction induced by a radioactive beam and this constitutes an excellent device to remove the background due to the radioactivity of the beam. The first results of this experiment will be reported.
